# Innovations in 3D Printing for Mechanical Component Fabrication

**Dr. Wei Han**

*Department of Science, School of Science and Technology, Singapore.*

## ABSTRACT

*Three dimensional printing, also known as additive manufacturing (AM) is a disruptive technology in production of mechanical parts. In comparison with conventional processes of subtractive fabrication, 3D printing allows the creation of complex shapes in layers directly off of a computer-generated model, with no limit on design freedom, material control, or precision, providing room like never before, to include anything imaginable within an object, and tailor it to individual preferences. Important advances have been made in recent years on both materials, manufacturing processes, and methods of computing design such that 3D printing is no longer applied to rapid prototyping but to the production of end-use mechanical parts. The given paper is a review and analysis of the recent breakthroughs in 3D printing technologies as means of fabricating mechanical components. The focus is made on the developments in the material sphere, multiprematerial printing, optimization of the process, hybrid manufacturing strategies, and integration of digital design. Designed literature search factors into studies of the existing research fashions, levels of performance and comparative research in principal additive manufacture strategies comprising fused deposition modeling, selective laser melting, electron beam melting and digital light processing. In addition, a complex methodology is put forward to analyze mechanical performance, dimensional accurateness, and production efficiency of additively manufactured parts. The available studies provide experimental results which are critically discussed to bring out positive strengths, weakness and suitability of application. The paper will conclude by determining the important obstacles and areas of future research to improve reliability, scalability and industry implementation of 3D printing to fabricate, mechanical parts. The evidence provided in this paper will be of sufficient value to advance into practice in the field of research, engineers, and industry practitioners who may use the findings in their comprehensive understanding of additive manufacturing innovations to apply innovative capabilities in mechanical engineering.*

## 1. INTRODUCTION

### 1.1. Background

Traditional methods of subtractive manufacturing like machining, casting and forging have long been used in fabrication of mechanical components, as these processes are known to exhibit precision, structural integrity and a proven industrial standard. Nonetheless, such processes normally entail the purification of bulk stock by eliminating the excessive amounts resulting in significant material wastage and higher production expenses. Moreover, the specialized tooling and molding requires necessitate initial high investments and longer lead times especially on complex or low-volume parts. The drawbacks of the conventional methods of manufacture have become more evident as modern engineering projects require lightweight structures, superior performance and customization of components. Additive manufacturing also known as 3D printing has come up in response to such challenges as one of those manufacturing paradigms that have revolutionized manufacturing. In contrast to subtractive approaches, 3D printing creates parts by layer directly based on the available digital models, which reduces materials wastage to a minimum and allows the effective utilization of resources. This digital-to-physical process permits designers to make complicated geometries, such as internal channels, lattice forms and forms optimized by topology, which are challenging or unattainable to accomplish through traditional processes. Moreover, in additive manufacturing, there is fast prototyping and design iterability and fast product development and customization without significant cost penalty. Such benefits have made 3D printing an attractive option to the next-generation fabrication of mechanical components, encouraging the development of this technology in terms of material, process, and performance.

### 1.2. Evolution of 3D Printing Technologies

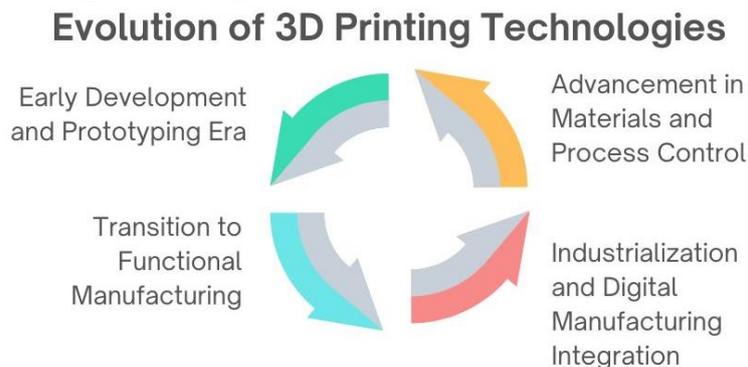

**Fig 1 - Evolution of 3D Printing Technologies**

#### 1.2.1. Early Development and Prototyping Era

The development of the 3D printing technologies started in the late 1980s with the birth of the early additive manufacturing processes that were mainly focused on a quick prototyping process. Such technologies like stereolithography as well as the fused deposition modeling were first created to develop visual and functional prototypes that could shorten the development cycle of products. In this stage, there were constraints in the materials, mechanical properties were not so good and the application was very restricted to only concept validation and not to the end-use constituents. However, these prototypical systems proved that it is possible to build layer-by-layer and formed the basis of future improvement.

### 1.2.2. Transition to Functional Manufacturing

As the research advanced, 3D printing was no longer used in prototyping, but it became aimed at creating useful components. The release of better machine accuracy, process control and development of better material formulations made possible the creation of better dimensional accuracy components and better mechanical performance. Technologies based on polymer materials were also developed to incorporate thermoplastics of engineering grade, and novel metal additive manufacturing methods like powder bed fusion and directed energy deposition were developed. This move was a big milestone in that additive manufacturing had started to be regarded as a tooling, fixtures, and low-volume functional components.

### 1.2.3. Advancement in Materials and Process Control

The second step in the development of 3D printing was promoted by the great achievements of materials science and optimization of the process. The invention of high-performance polymers, fiber-reinforced composites, and special metal alloys contributed a lot to the strength, fatigue, and thermal stability. At the same time, there was enhanced process monitoring, simulation tools and parameter optimization techniques which made builds very reliable and repeatable. Such developments saw additive manufacturing being able to fulfill more rigid industrial demands and found increased use in the aerospace and automotive industries as well as in biomedical.

### 1.2.4. Industrialization and Digital Manufacturing Integration

During the recent years, 3D printing has become an important aspect of digital manufacturing and Industry 4.0. The contemporary system of additive manufacturing is more and more combined with digital design and simulation, or data-driven optimization. The productivity and quality have been further advanced by automation, real-time monitoring, and hybrid production methods that combine additive and subtractive production with the help of hybrid technologies. This development portrays the shift of 3D printing as a niche technology to a strategic manufacturing solution with the role of making industrial mechanical parts of high performance.

## 1.3. Innovations in 3D Printing for Mechanical Components

Recent advances in 3D printing have seen the use of this technology extended far beyond the scope of prototyping to include the production of mechanical parts such that this technology is considered a valid production technology. The development of computational design tools like topology optimization and generative design is one of the most significant developments as they provide the possibility to produce lightweight, high-strength components with optimized load paths. These design approaches fully utilize the geometric liberty of additive manufacturing, which facilitates the production of complicated lattice designs and internal types of features that can promote the strength of mechanical operations and cut material overheads. Innovation in the materials has also been a determining factor in the development of mechanical applications. The introduction of the high performance thermoplastics, metal alloys designed to fit in additive processes and fiber reinforced composites has enhanced strength, stiffness, fatigue, and thermal stability. Ongoing fiber reinforcement within polymer printing, such as has allowed making components with mechanical characteristics comparable to conventional composite. Refined powder properties and alloy compositions in metal additive manufacturing have resulted in better microstructural results and less defect development. Innovations to processes, such as measurement of advances in the process monitoring, closed-loop control systems, and methods of better energy delivery have improved consistency of the build and quality of the parts. The defects can be detected in real-time during the fabrication, and the corrective measures can be taken to enhance reliability

and repeatability. Also, combined manufacturing strategies that entail the integration of additive manufacturing and conventional machining have become effective strategies in the attainment of high dimensional precision and excellent surface finish. These innovations combined have broadened the responsibility of 3D printing in mechanical engineering to include manufacturing of custom, high performance parts applicable to aerospace, automotive, bio medical, and industrial systems. With the technology now becoming a new reality, additive manufacturing is taking more and more of a complementary nature, and in certain instances, alternatives to the traditional method of fabricating components mechanically.

## 2. LITERATURE SURVEY

### 2.1. Overview of Additive Manufacturing Techniques

Additive manufacturing (AM) refers to a set of layer-by-layer fabrication methods which vary in energy source, form of feedstock and consolidation mechanism, meaning each method is appropriate to particular mechanical applications. Fused Deposition Modeling (FDM) is highly used in prototyping and low-load applications because it is inexpensive, it uses materials available on-hand and its layer-by-layer deposition process makes it cost-effective, whilst giving it anisotropic mechanical behavior. Selective Laser Melting (SLM) and Electron Beam Melting (EBM) processes in which metal is used to create fully dense high-strength components used in structural and aerospace applications is feasible, but it demands a large amount of energy input and a complex control mechanism. Diversity Techniques Vat photopolymerization processes such as Digital Light Processing (DLP) are preferable due to high surface finish and dimensional resolution, which are suitable in processes requiring precision components, although there is a restriction in material diversity and long-term mechanical stability. All these technologies demonstrate the trade-offs of additive manufacturing in terms of cost, performance, and scope of application.

### 2.2. Material Innovations in 3D Printing

The progress in material science has played a strong role in expanding the application of the additive manufacturing to mechanically challenging systems. High-performance thermoplastics such as polyether ether ketone (PEEK) and polyetherimide (PEI) have good strength to weight ratios, thermal stability, and chemical stability, and thus can be used in aerospace and biomedical parts. Also, polymer incirclement with short or interminutes carbon and glass fibers has majorly contributed to the improvement of polymer fatigue, strength, and stiffness. In additive manufacturing with metals, microstructural control, fatigue resistance, and thermal stability have been improved because tailored alloys and optimized powder chemistries have developed. These materials innovations have transformed AM to an end-use mechanical component prototyping tool to a manufacturing alternative.

### 2.3. Mechanical Performance Studies

There is a large amount of experimental evidence of the mechanical behavior of additively manufactured components under different loading conditions. Tensile, compressive, fatigue, and fracture studies are all consistent that process parameters have a great impact on mechanical performance. Porosity, residual stress and microstructural anisotropy depend on factors like layer thickness, scanning strategy, print orientation and energy density which impact on strength and durability. Comparative studies of additively manufactured parts and conventionally manufactured ones show that although additive manufactured parts can be produced with similar statical strength, they usually exhibit the different fatigue behavior and failure mechanisms as a result of the process-

vitreous defects inherent in these parts. These results highlight the need to optimize processes and discipline parameters in order to get gained reliability of mechanical performance.

**2.4. Identified Research Gaps**

In spite of the significant advances in the technologies and materials of additive manufacturing, there are still several essential issues to be addressed. The layer structure of AM processes and the existence directional microstructures allow achieving isotropic mechanical properties to be challenging. They also have poor reproducibility and consistency between builds which makes them inapplicable to large scale industrial use. In addition, limited standards and design specification of load bearing and safety critical applications makes it a limiting aspect in the engineering practice. The future reliability information especially with regard to fatigue, creep, and environmental degradation is lacking. Sealing these loopholes by way of a structured experimentation, modeling, and standardization is critical to the maturation of additive manufacturing as a mainstream manufacturing technology.

## 3. METHODOLOGY

**3.1. Research Framework**

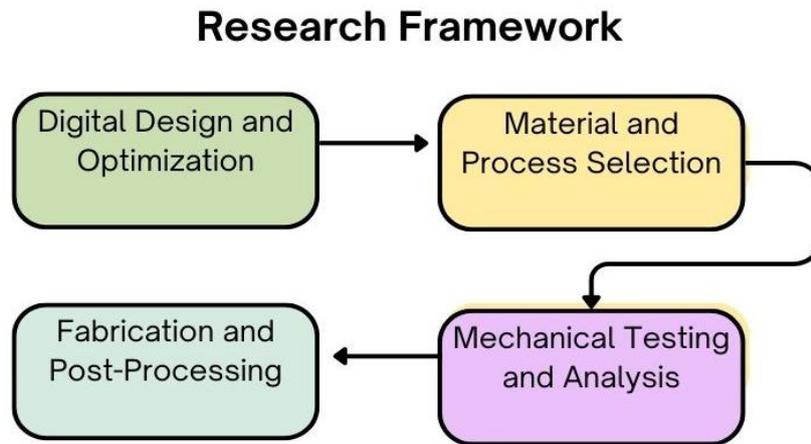

**Fig 2 - Research Framework**

*3.1.1. Digital Design and Optimization*

The study starts with digital design of mechanical parts with computer-aided design (CAD) software. Topology optimization methods and finite element analysis (FEA) are the design optimization methods used to ensure that the weight is minimized, load distribution is improved and structural efficiency is enhanced whilst ensuring that the functions are not compromised. The stage will make sure the geometry is conducive to the limitations of additive manufacturing, such as overhangs, support ventures, and layer-based manufacture.

*3.1.2. Material and Process Selection*

After design optimization, the relevant materials and additive manufacturing procedures are chosen with regard to desired mechanical performance and use criteria. Factors to be taken into consideration are the strength of the material used, thermal stability and fatigue resistance and the compatibility with the technology that is selected to be used in printing. Process parameters typically include; layer thickness, build orientation, energy input and scanning strategy; they are designed to bring out the best part quality and repeatability.

### 3.1.3. Fabrication and Post-Processing

The optimized designs are produced by selective manufacturing technique that is under controlled conditions. Support removal, heat treatment, surface finishing or machining is carried out as needed to enhance dimensional precision, surface quality, and mechanical characteristics. These measures are important in eliminating stress-leftovers, decreasing the number of defects, and improving overall component functioning.

### 3.1.4. Mechanical Testing and Analysis

Experimental appraisal of the fabricated parts by the use of mechanical testing like tensile, compression, hardness, and fatigue is the last phase. The results obtained are examined to determine how design decisions, choice of material and process parameters affect mechanical behavior. This discussion gives the understanding of the performance tendencies and approves the efficiency of the offered methodology to fabricate mechanical components additively using the additive manufacturing process.

## 3.2. Design and Computational Optimization

Computational optimization and design constitute an important phase in the facilitation of the performance of additively manufactured mechanical elements. This work reported methodically optimizes the computer-aided design (CAD) models with topology optimization techniques that strive to realize lightweight models without compromising the necessary mechanical strength and stiffness. Topology optimization operates by reassigning material in a defined design space eliminating areas of inefficiency that do not perform much load carrying, and only keeping material where it is structurally required. The latter would be well suited to additive manufacturing, where complex geometries produced by optimization can be easily created without the limitations of the traditional manufacturing process. This optimization process is defined by an objective function that aims at the minimization of the structural compliance of the component which is a measure of the total compliance of the component under applied loads. Simply put Compliance is the strain energy that is accumulated in the structure when it is exposed to external forces. Reducing this amount ensures that design achieved after optimization has maximum stiffness and efficient load transfer. This can mathematically be stated as the volume integral of the product of stress and strain in the entire type of design domain, which refers to the total elastic energy of the material. The optimization is carried out taking certain constraints to ensure the designs are practical and safe. A volume constraint restricts the available material and hence imposes weight loss targets and enhances the efficiency of materials. Stress limits are also enforced so that the excessive concentrations of stress can not cause premature failure or fatigue damages. These limits guarantee that the optimization of geometry results in a minimisation of mass, besides meeting strength and life requirements. This process is then followed with optimization of the CAD model that is then proven by numerical simulations like finite element analysis to ensure that it structurally works. The combination of topology optimization and computational analysis permits the generation of mechanically beneficial, lightweight designs that have been optimized to be used with additive manufacturing and eventually enhance the component performance and material usage.

## 3.3. Process Parameter Selection

The choice of process parameters is a crucial factor in deciding the quality, reliability, and mechanical performance of additively manufactured parts. Parameters of additive manufacturing, like print speed, layer height, orientation of the build, energy input will directly affect part density, surface finish, microstructural features and development of residual stress. The first to consider is

improper parameter choice which may lead to defects like porosity, poor interlayer bonding, dimensional errors, and anisotropic behavior under loads and as a result of systematic parameter optimization is very important to produce components of difficult mechanical qualities. The rate of material deposition or fusing is determined by the print speed, and bonding between the layers is greatly influenced by print speed. The combination of too high and too low speed can result in inadequate mixage and too much heat and residual stresses respectively. Surface resolution and mechanical strength depends on the layer height; there is generally an enhancement of interlayer bonding and dimensional accuracy with thinner layers, but a reduction in productivity with thicker layers. The other important parameter is that in order to define anisotropy, tensile strength, and fatigue life, build orientation determines the direction of layer stacking in comparative to applied loads. The amount of material consolidation and refinement of the microstructure depends on the amount of energy input which is regulated by laser power, electron beam current or extrusion temperature. In order to effectively determine the synergistic effects of these parameters, a Design of Experiments (DoE) technique is used. DoE allows the simultaneous systematic variation of a large number of parameters and also reduces the number of experimental trials that need to be done. The method helps to identify important factors, combinations between parameters, and best parameter ranges to produce elevated mechanical characteristics and process stability. The quantitative evidence on the sensitivity of parameters and repeatability of the experiment is acquired through statistical analysis of the experiment. This organized method facilitates the use of data in decision-making and promoting the consistency of the fabrication used in the manufacturing of mechanical parts through additive manufacturing by combining DoE with process monitoring and mechanical assessment of the fabrication.

### 3.4. Mechanical Testing Protocol

To be a part of the proposed methodology, mechanical testing plays a significant role as it makes quantitative confirmations of the structural integrity and performance of additively manufactured parts. Tensile, compression, and fatigue testing are also known as standardized mechanical tests that are carried out to ascertain that the outcomes are consistent, repeatable, and comparable to the literature and typical manufacturing standards. All tests are conducted in line with the global standards like of ASTM and ISO, that specify the geometry of the specimen, testing conditions, loading rates and reporting data protocols. By sticking to these standards, the experimental bias will be minimized, and parallel batches of tests will be more consistent. Basic mechanical characteristics that tensile testing is used to measure include ultimate tensile strength, yield strength, elastic modulus, and elongation at failure. Compression testing helps in giving an idea on the availability of load-bearing capabilities, deformation characteristics, and failure characteristics under compressive loading which is especially applicable in structural and support components. Fatigue testing is also performed with cyclic loading to determine how long the fabricated parts will last and perform at long loads because fatigue behavior commonly functions as a constraint in the load-bearing performance. Specimens are exposed to various orientations that would work on varying directions of builds to resonate the impacts of anisotropy in additive manufacturing. In order to evaluate the consistency and reliability of the experiment findings, statistical analysis of the data obtained is conducted. Variability across samples can be measured using such things as mean values, standard deviation, and coefficient of variation. The repetition is assessed by comparing the outcomes obtained with several specimens created in the same conditions. Such a statistical model provides the opportunity to identify the variations caused by processes and conduct a credible analogy among various materials, process settings, and other design options, which leads to performance verification and process validation.

# 4. RESULT AND DISCUSSION

## 4.1. Mechanical Property Evaluation

The experimental findings that have been found during this study indicate that, under the right design strategies and careful process parameter considerations, additively manufactured parts have potential to obtain mechanical properties that are similar to that of end products manufactured through the traditional manufacturing process. Optimized build parameters, as suggested by tensile and compressive test results, create a substantial upgrade in strength, stiffness, and ductility by increasing interlayer bonding and minimizing effects caused by processes such as porosity and absence of fusion. In additive manufacturing achieved with polymer materials, print orientation, layering, extrusion temperature, and subsequent stress patterns are known to assist in forming more homogeneous stress distribution and low anisotropy, making mechanical behavior with more homogeneous values comparable to that of injection-molded components. Powder bed fusion additive manufacturing technology can also use metal as a single appropriate material, and powdered metals are enriched with crystalline microstructures and high densities resulted in better strength and load-bearing capacity. Through experimental studies, to achieve high yield performance and tensile strength, optimized energy input and scanning strategies allow superior metallurgical bonding and reduction of internal defects. Nevertheless, in spite of these benefits, roughness and unresolved stresses on the surface still constitute the natural problems of metal additive manufacturing. Consequently, after processing processes, including heat treatment, hot isostatic pressing and surface finishing, are commonly needed to enhance surface quality, dimensional fidelity as well as fatigue performance. Compared analysis with surprising components traditionally manufacturing demonstrates that although similarities in the similarity of the mechanical properties of the statistic will be achieved, or even overtaken, distinctions in the behavior of fatigue and fracture may still remain unchanged. The main causes of these differences are considered to be the imperfections of the surface and the microstructural heterogeneity that is gained in the course of the additive process. Generally speaking, the findings indicate that additive manufacturing with the help of parameter optimization and proper post-processing can be considered a valid manufacturing method of high-performance mechanical parts, especially where the flexibility of the design and minimization of weight pose critical considerations.

## 4.2. Dimensional Accuracy and Surface Quality

The most important performance indicators of additively manufactured mechanical components are dimensional accuracy and surface quality, especially those that demand tight tolerances and high reliability assembly. The findings have shown that the causes of dimensional variation of printed parts are mainly due to thermal distortion, non-uniform cooling, and material shrinkage during the fabrication of printed parts after each layer is built. Residual stress and warping are caused by steep thermal gradients in localized heat sources (metal additive manufacturing) and volumetric shrinkage in solidification (polymer-based manufacturing) which results in geometry errors. Such effects become more evident in complicated geometries, thin-walled, and components with large unsupported features. Process properties that are also associated with strongly affecting the surface quality include layer thickness, energy input and scanning strategy. The stair-step effect of layered fabrication per se leads to more surface roughness especially in inclined and curved surfaces. Also metal printing is characterized by partially melted particles hence worsening surface finish as well as polymer extrusion processes that suffer irregular flow of material thereby worsening surface finish. Experiments have verified that roughness of surfaces and aesthetic quality are interdependent as well as roughness has a major influence on the mechanical performance in terms of fatigue behavior, with surface defects potentially serving as a locus of crack initiation. The Post-

processing methods have been demonstrated to be very useful in reducing such restrictions. Machining processes, e.g. milling, turning, are also derived to provide notable dimensional accuracy, i.e. to eliminate the surplus or rectify the geometric deviation. The heat treatment procedures are used to eliminate the remnant strains, distortions as well as stabilizing the components dimensions. Surface finishing can be used in other instances to further improve the surface quality using surface finishing methods like: polishing, shot peening or chemical treatment. The additive manufacturing process combined with potential use of post-processing permits the manufacture of parts both of tight dimensional and surface quality standards to enlarge the potential use of additive manufacturing in making highly accuracy mechanical parts.

### 4.3. Comparative Performance Analysis

**Table 1: Comparative Performance Analysis**

| Manufacturing Method | Tensile Strength (%) | Fatigue Life (%) |
|---|---|---|
| Conventional Machining | 100% | 100% |
| SLM | 96.20% | 80% |
| FDM Composite | 61.50% | 30% |

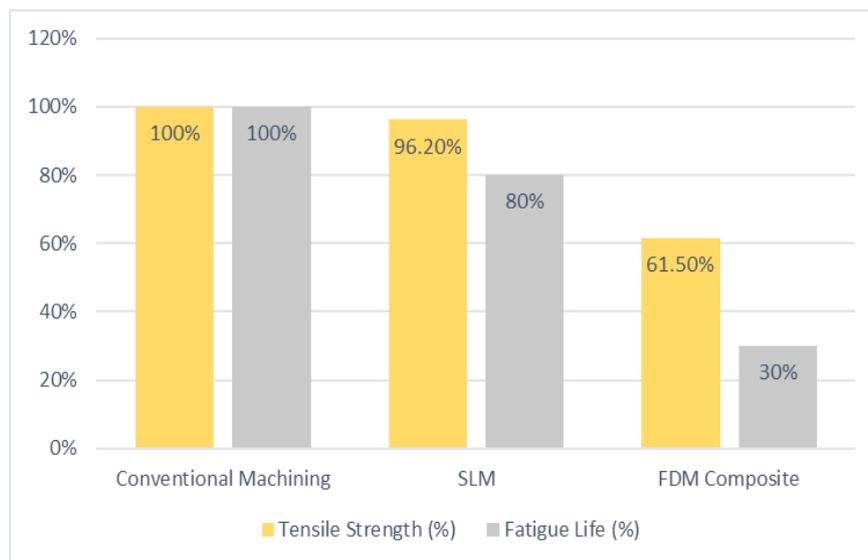

**Fig 3 - Comparative Performance Analysis**

#### 4.3.1. Conventional Machining

When comparing mechanical performance, conventional machining is used to determine the tensile strength and fatigue life, as the values of conventional machining were obtained as 100 percent. This is believed to be due to well-developed processing paths, homogeneous material microstructures and the minimum number of internal defects. Machined parts usually exhibit predictable mechanical properties and high levels of fatigue behavior and are therefore used in safety-toxic and load-bearing applications. This has led to the fact that conventional machining finds its way as a comparison on the scale against which the additive manufacturing techniques are evaluated.

#### 4.3.2. Selective Laser Melting (SLM)

ELM has a tensile strength of about 96.2 percent and a fatigue life of about 80 percent of that of the traditional machining. The great tensile performance of SLM components results mainly

because of superfine microstructural features and substantial material density which appear to be created during rapid solidification. Lessened life of fatigue is observed though because of surface roughness, remaining residual stress, and microscopic porosity of the process. Through proper post-processing tools like heat treatment or surface finishing, the fatigue performance of SLM components can be increased further reducing the difference with parts produced by other conventional methods.

### 4.3.3. FDM Composite

FDM composite materials have considerably lower mechanical performance with tensile strength scores of 61.5 percent and a fatigue life ratio of 30 percent in comparison with conventional machining. These are majorly caused by anisotropic behavior of the material, low interlayer bonding and the existence of voids in the printed structure. Although incorporation of the reinforcing fibers improves the stiffness and strength as compared to unreinforced polymers, there is low fatigue resistance. The FDM composite parts, therefore, are better used in lightweight and non-sensitive or moderately loaded applications than in high-performance structural applications.

### 4.4. Industrial Implications

As the results of this research paper indicate, additive manufacturing represents a great industrial prospect in manufacturing tailored and low-volumetric mechanical parts. The capability to print complex geometries and application-specific designs without any specific tooling is one of the most striking benefits of 3D printing. It allows manufacturing in a speedy fashion, being able to design and iterate on designs faster and even in batches, and allows additive manufacturing to be especially appealing in industries with a high dependency on complexity and customization of parts, including aerospace, biomedical, automotive, and tooling. The shorter lead time and digital workflow is also applicable to decentralized manufacturing and on-demand production that would help in reducing inventory expenses and enhancing the flexibility of the supply chain. Although these are the benefits, the cost and scalability are the significant issues that restrict the mass production of products to additive manufacturing. The production costs are not only high due to the high equipment cost especially metal based systems and high fine cost of raw materials including metal powder and high performance polymers. Besides that, comparatively low building speed in comparison with the conventional manufacturing process limits throughput making large scale production uneconomical. Additional manufacturing time is required and additional costs incurred in post-processing needs such as heat treatment, machining and surface finishing. Process quality assurance and reliability is another industry factor. Unpredictability in both mechanical characteristics and dimensional accuracy and surface finish may provide obstacle to large-scale manufacturing. The strictness of regulatory and safety standards in industries also necessitate standardized processes of qualification to which additive manufacturing technologies are still underdeveloped. In general, although additive manufacturing has a high potential of customized, lightweight and low-volume mechanical elements, the development of increasing automation in the process, reducing the costs of materials and standardizing it is necessary in order to transform the shift of additive manufacturing with niche use to mass production of industry products.

## 5. CONCLUSION

This paper has demonstrated in greater detail the recent developments in 3D printing technologies in fabrication of mechanical components and their increasing importance in sophisticated engineering. Important advances in additive manufacturing have been catalyzed by the related advances in material development, process optimization, and material design methodologies. Strength, stiffness and thermal stability have been significantly enhanced with the introduction of

high-performance polymers, reinforced composites and optimized metal alloys, thus allowing additively manufactured components to be capable of fulfiling functional and structural requirements that would otherwise be possible only with traditional manufacturing processes. Also, the incorporation of computational design methods like topology optimization and finite element analysis have increased the efficiency of materials, and it is now possible to use computer-aided designs to create lightweight performance-driven components with complex geometries. As the findings brought up in the present work show, provided with optimal process settings and proper post-processing, additive manufacturing can yield the mechanical components which have properties similar to the ones of the part machined traditionally. Specifically, load-bearing applications have demonstrated a high future potential of metal-based additive manufacturing processes, but the quality of the surfaces and fatigue performance are frequently subjected to secondary treatment. The printing techniques that involve polymers and composite have been advantageous with respect to cost, weight, and designs allowing it to be appropriate in customized products with low volume production conditions. Nevertheless, such intrinsic issues like anisotropic behavior, defects introduced by the processes, dimensional variation still affect the mechanical performance and reliability. Although this potential has been demonstrated, there are a number of important limitations that should be overcome before additive manufacturing can become a full-scale source of large-scale industrial production. The unintegrated standards, small amount of long-run performance data, and scalability and cost-efficiency issues are still considerable obstacles. Moreover, to be accepted by industry, especially by the safety-critical sectors, it is important that quality and repeatability between machines, materials and operating conditions should be consistent. The future research study ought to dwell on the hybrid manufacturing methods that integrate additive and more traditional manufacturing methods in order to take advantage of both. Reliability and repeatability can also be advanced through the more advanced use of real-time process monitoring systems, data-driven control systems, and optimization based on machine learning. Another factor that will help in boosting industrial adoption is the creation of standard design requirements and qualification formats. All in all, the information included in this paper leads to a better understanding of additive manufacturing capabilities and drawbacks and benefits its further use in the contemporary mechanical engineering practice and its future development as a mature and technologically suitable manufacturing process.
